#### Introduktion

Sufficient lymph node yield for patients with head and neck cancer undergoing neck dissection is associated with improved overall survival and lower rates of local-regional failure. However, variables to affect the lymph node yield in neck dissection remain unknown. The aim of this study was to determine factors affecting the yield of lymph nodes.

#### Materiale/metode

Two hundred and twenty-one patients surgical treated for oral cavity carcinoma with additional level 1-3 neck dissection (from 2017-2022) were included. The total number of lymph nodes identified in the excised specimen was recorded in each case. A univariate analysis was performed to ascertain whether this number was significantly influenced by any of several variables.

## Resultater

No correlation between number of yielded lymph nodes and sex (P=.97), weight (P=.06), BMI (P=.10), age (P=.85), current smoking (P=.89), alcohol abuse (P=.86), tumor staging (P=0.99), or lymph node metastasis (P=.73) were found. However, excluding patients with severe obesity defined as BMI>35, increasing BMI (P=.04, coef=0.36) and weight (P=.03, coef=0.10) were correlated with increasing number of yielded lymph nodes. Furthermore, previous radiation therapy of the neck was associated with a significant lower number of yielded lymph nodes (P=0.02, coef=-4.74).

## **Diskussion**

Only previous radiation therapy of the neck was associated with a reduced number of yielded lymph nodes during level 1-3 neck dissection. A tendency toward a positive correlation between increasing weight and BMI and number of yielded lymph nodes was found. However, it was only significant if patients with severe obesity were excluded.
